In very broad strokes, our goal is extract quantum groups from factorization algebras defined on certain manifolds. For some examples the manifold is simply a copy of Euclidean space. The Yangian quantum group will come from a factorization algebra on $\mathbb{C} \times \mathbb{R}^2 = \mathbb{R}^4$, where, in some sense, we remember the complex structure on the copy of Euclidean space $\mathbb{C} = \mathbb{R}^2$.

1. What is a factorization algebra?

Let $X$ be a manifold. (Think: spacetime.)

A *prefactorization algebra* $\mathcal{F}$ on $X$ is:

- a vector space $\mathcal{F}(U)$ for each open set $U \subset M$
- a linear map $\mathcal{F}(U) \rightarrow \mathcal{F}(V)$ for each inclusion $U \subset V$
- a linear map $\mathcal{F}(U_1) \otimes \cdots \otimes \mathcal{F}(U_n) \rightarrow \mathcal{F}(V)$ for each $U_1, \ldots, U_n \subset V$ with the $U_i$ pairwise disjoint.

satisfying

- equivariance under relabeling
- associativity under composition: if $U_{i,1} \sqcup \cdots \sqcup U_{i,n_i} \subseteq V_i$ and $V_1 \sqcup \cdots \sqcup V_k \subseteq W$, the following diagram commutes:

\[
\begin{array}{ccc}
\bigotimes_{i=1}^k \bigotimes_{j=1}^{n_i} \mathcal{F}(U_j) & \longrightarrow & \bigotimes_{i=1}^k \mathcal{F}(V_i) \\
\downarrow & & \downarrow \\
\mathcal{F}(W) & & 
\end{array}
\]

A prefactorization algebra $\mathcal{F}$ on $X$ is a *factorization algebra* if it satisfies a certain gluing condition. Note that this is not the ordinary gluing condition saying that the underlying precosheaf $\mathcal{F}$ determines is a cosheaf.

The main result of Costello [Cos] that we study in this seminar relates the geometry of a four-dimensional gauge theory to the algebra of quantum group deformations. The connection to gauge theory and factorization algebras is the guiding principal of Costello-Gwilliam [CG17, CG]:

*The observables, or operators, of a quantum field theory have the structure of a factorization algebra.*

On the geometric side, this says that once one takes into account a sufficient amount of locality on the manifold, the functions on the moduli space of connections (or more interestingly, a deformation thereof) form a factorization algebra in a natural way.
The following picture portrays the general landscape of the theory of factorization algebras.

\begin{center}
\begin{tikzcd}
\{ \text{Chiral/vertex algebras} \}
& \{ \text{Factorization algebras} \}
& \{ \text{Locally constant factorization algebras} \}
& \{ \mathcal{E}_n \text{ algebras} \}
\\
\{ \text{Algebras over other (colored) operads.} \}
& (\text{Riem, cplx, conformal, ...})
\\
\end{tikzcd}
\end{center}

Perhaps the most well-known class of factorization algebras are the *locally constant* ones. These are factorization algebras defined on a smooth manifold that roughly only depend on homeomorphism type of the manifold. In particular, this class of factorization algebras see no difference between open balls of varying radius. It is a theorem of Lurie [Lur] that this class of factorization algebras is equivalent to the theory of $\mathcal{E}_n$-algebras; algebras over the operad of little $n$-disks.

This is quite a restrictive class of factorization algebras. In addition to locally constant factorization type, we will also encounter factorization algebras that *holomorphic*. These are algebras that are sensitive to complex structures.

**Example 1.1.** If $E$ is any (graded) vector bundle on a manifold $X$, we can form the infinite symmetric product

$$\text{Sym}^\ast(E) = \mathbb{C} \oplus E \oplus \text{Sym}^2(E) \oplus \cdots .$$

This is an infinite dimensional vector bundle on $X$, with a nice topology coming from the natural filtration by symmetric degree.

**Fact 1.2.** For any vector bundle, the cosheaf of compactly supported sections of $\text{Sym}^\ast(E)$:

$$U \subset X \mapsto \Gamma_c(U, \text{Sym}^\ast(E))$$

has the structure of a factorization algebra.

All of the examples of factorization algebras we encounter in this seminar arise as deformations of ones of this form (or by replacing compactly supported sections by distributional compactly supported sections).

1.1. **The observables of a QFT.** It is completely geometric that the *classical* observables (function on sections of some vector bundle) have the structure of a factorization algebra. Generically, these factorization algebras have the form

$$\text{Obs}^{cl} = \left( \text{Sym}(E^\vee), Q^{cl} \right) ,$$
where $Q^{cl}$ is the classical differential. In the contexts we have addressed, the classical differential behaves like a Chevalley-Eilenberg differential computing Lie algebra cohomology.

The Batalin-Vilkovisky formalism is an approach developed by Costello in [Cos11] to construct the path integral in a rigorous way. At the level of observables, a quantization produces a factorization algebra of the form

$$\text{Obs} = \left( \text{Sym}(\mathcal{E}^\vee)[[\hbar]], Q_\hbar = Q^{cl} + \hbar Q^{(1)} + \hbar^2 Q^{(2)} + \cdots \right),$$

where $Q_\hbar$ is the quantum differential.

There is a precise analogy of the BV formalism with ordinary deformation quantization. The classical observables are always equipped with some structure of a (shifted) Poisson algebra. The factorization algebra of quantum observables deforms this Poisson structure.

Extreme care must be taken when defining the quantum differential rigorously. This is related to the difficulties in defining the path integral. For instance, naively the terms in the differential $Q^{(i)}$ for $i \geq 1$ have support everywhere on the spacetime manifold. This makes the process of defining the factorization algebra, which is really a local object, a tricky one.

2. Prelude: Chern-Simons and Quantum Groups

Chern-Simons theory is a three-dimensional topological field theory consisting of flat connections of a principal $G$-bundle. The moduli space of the solutions to the classical equations of motion of Chern-Simons on a three-manifold $M$ is $\text{Flat}_G(M)$, the moduli space of $G$-local systems on $M$. If $A$ represents a connection on a principal $G$-bundle, flatness is the equation

$$F(A) = dA + \frac{1}{2} [A, A] = 0.$$

Witten [Wit89] showed that quantum Chern-Simons theory is intimately connected to knot invariants, specifically, the Jones polynomial. As a result, Chern-Simons theory is indirectly related to the theory of quantum groups.

In the style of physics, Chern-Simons theory is described by an action functional depending on some connections of principal $G$-bundles over a three-manifold. The critical values of the action functional precisely correspond to flat $G$-bundles. Two flat $G$-bundles are said to be equivalent if they differ by a $G$-valued gauge transformation. The moduli space of flat $G$-bundles is the space of flat connections modulo gauge. Of course, this is a highly singular object, so one must consider it as an appropriate stacky object.

Suppose the three-manifold we are studying is of the form $M = \Sigma \times \mathbb{R}$, where $\Sigma$ is a Riemann surface. The moduli space of flat $G$-bundles that are constant in the direction of $\mathbb{R}$ is of the form

$$\text{Flat}_G(\Sigma) = \{\text{Flat } G\text{-bundles on } \Sigma\} = \text{Hom}(\pi_1(\Sigma), G)/G$$

We will assume that $G$ is a complex semi-simple group.

**Fact 2.1.** The space $\text{Flat}_G(\Sigma)$ is a symplectic manifold.
If $A$ is some reference flat connection for a principal $G$-bundle $P$ on $\Sigma$, then the tangent space of the moduli space of flat $G$-bundles at $A$ is the first order deformations of $A$ in the space of all flat $G$-bundles. We must still take the quotient by gauge transformations. That is:

$$T_{A, \text{Flat}_G}(\Sigma) = \{ \tilde{A} \in \Omega^1(\Sigma, g_P) \mid A + e\tilde{A} \text{ is flat} \}/\text{gauge}$$

Here, $e$ is a formal parameter such that $e^2 = 0$. Also, $g_A$ is the adjoint bundle of $P$, it is a bundle of Lie algebras with fiber $g = \text{Lie}(G)$. The notation $g_A$ is to remind us that we are equipping it with the flat connection $A$.

Since $A$ is flat, the condition that $A + e\tilde{A}$ is flat is equivalent to

$$d_A \tilde{A} = d\tilde{A} + [\tilde{A}, A] = 0.$$  

Here, $d_A = d + [A, -]$ is the covariant derivative with respect to $A$. Moreover, the gauge transformations $f \in \Gamma(\Sigma, g_P)$ act by

$$\tilde{A} \mapsto d_A f$$

Thus, we see that $T_{A, \text{Flat}_G}(\Sigma)$ is precisely the cohomology group $H^1(\Sigma, g_P)$.

If $\tilde{A}, \tilde{A}' \in T_A H^1(\Sigma, g_P)$ we define the symplectic form

$$\omega_A(\tilde{A}, \tilde{A}') = \int_{\Sigma} \langle \tilde{A}, \tilde{A}' \rangle_g$$

where $\langle -, - \rangle_g$ is the Killing form on $g$. Note that the integrand on the RHS is a two-form so it can be integrated.

The full, derived tangent space, can be identified with $\Omega^*(\Sigma, g_P)[1]$ equipped with the differential $d_A = d + [A, -]$. Note that $\Omega^*(\Sigma, g_P)$ has the structure of a dg Lie algebra, and the Maurer-Cartan elements are precisely deformations of the flat connection $A$. This is a generic property of formal moduli, and more relevant to us, perturbative field theories.

Quantum Chern-Simons on $\Sigma \times \mathbb{R}$ essentially reduces to studying deformation quantization for the symplectic manifold $\text{Flat}_G(\Sigma)$. The operators of the classical theory are just the functions on the symplectic manifold $\Omega(\text{Flat}_G(\Sigma))$. Symplectic structure equips this with a Poisson bracket. A deformation quantization is an algebra of the form $\mathcal{O}_h(\text{Flat}_G(\Sigma))$ whose associative product satisfies

$$a, b \in \mathcal{O}_h \implies \lim_{h \to 0} \frac{1}{h} [a, b] = \{a, b\}.$$  

If we work near the trivial connection on $\mathbb{R}^3 = \mathbb{R}^2 \times \mathbb{R}$ the moduli space $\text{Flat}_G(\mathbb{R}^2)$ is described by the dg Lie algebra $\Omega^*(\mathbb{R}^2, g)$. Functions on the moduli space are modeled on the Chevalley-Eilenberg cochain complex

$$\mathcal{O}(\text{Flat}_G(\mathbb{R}^2)) = C^*(\Omega^*(\mathbb{R}^2, g))$$

Note that as a cochain complex, there is a quasi-isomorphism $C^*(\Omega^*(\mathbb{R}^2, g)) \simeq C^*(g)$.

$$\begin{array}{ccc}
\mathcal{O}_h(\text{Flat}_G(\Sigma)) & \simeq & C^*_h(g) \\
\downarrow_{h \to 0} & & \downarrow_{h \to 0} \\
\mathcal{O}(\text{Flat}_G(\Sigma)) & \simeq & C^*(g)
\end{array}$$
This picture hints at a more direct relationship between Chern-Simons theory and the quantum group, without passing through the theory of knot invariants. Even so, knot invariants have a natural physical interpretation as line operators in the three-dimensional theory. This picture is compatible with the approach we take to obtain the quantum group via factorization methods.

2.1. Example: Chern-Simons factorization algebra. We’ve been a bit naive here, and never discussed the actual algebraic structure the deformation $C^*_h(g)$ possesses. To really understand this, we need to appeal to the theory of factorization algebras.

On a 3-manifold, the fields of Chern-Simons theory are also of this form:

$$\Omega^*(M^3) \otimes g[1].$$

By definition, the classical observables supported on an open set $U$ are defined as the functions on fields supported on $U$. Thus, for Chern-Simons, a linear observable on $U$ looks like a linear map of the form

$$O : \Omega^*(M) \otimes g[1] \rightarrow \mathbb{C}.$$

Using Poincaré duality, we can read off that the space of all observables supported on $U$ is

$$\text{Obs}^{cl}_CS(U) = \text{Sym}^* ((\Omega^*(M) \otimes g[1])^\vee) = \text{Sym}^* (\Omega^*_c(U) \otimes g^\vee[2]).$$

This cochain complex is equipped with the Chevalley-Eilenberg differential coming from the dg Lie algebra $\Omega^*(M) \otimes g$.

**Remark 2.2.** Strictly speaking, we should really use the distributional compactly supported sections.

Chern-Simons is the typical example of a topological field theory. In this setting, this means that the factorization algebra $U \mapsto \text{Obs}^{cl}(U)$ is locally constant. Indeed, for each disk $D$ the classical observables are quasi-isomorphic to the Chevalley-Eilenberg complex $\text{Obs}^{cl}(D) \simeq C^*(g)$. On the three-manifold $M = \mathbb{R}^3$ this implies, by Lurie’s theorem, that the observables determine an $E_3$-algebra. In fact, classically, this is actually a commutative (or $E_\infty$-algebra).

BV quantization picks out a deformation $\text{Obs}^q$ of $\text{Obs}^{cl}$ as locally constant factorization algebras on $\mathbb{R}^3$. Equivalently, BV quantization determines a deformation $C^*_h(g)$ of $C^*(g)$ as an $E_3$-algebra.

On one hand, we are claiming that the Koszul dual of this deformation of the quantum group. For Chern-Simons, the quantum group can be shown to also arise in the following, more geometric, way. This is currently work in progress of Costello-Francis-Gwilliam. The $E_3$-algebra has an associated category of modules $\text{Mod}_{\text{Obs}CS}$. By the general technology of factorization algebras, this category is equipped with an $\mathcal{E}_2$-monoidal structure (i.e. an $\mathcal{E}_2$-algebra in the category of categories). Concretely, this means there is a two-dimensional space in which one can take the tensor product of two modules. In geometric terms, we can view a module for the $\mathcal{E}_3$-algebra as living on a line in $\mathbb{R}^3$. The tensor product corresponds to an “operator product” of lines. Since the space orthogonal to a line in $\mathbb{R}^3$ is a copy of $\mathbb{R}^2$, this gives two directions in which a tensor...
product can take place. In more classical terms, $E_2$-monoidal categories arise as braided monoidal categories. It is known that the modules for a quasi-triangular Hopf algebra form a braided monoidal category. The connection to Chern-Simons is the following:

**Theorem 2.3** (Costello-Francis-Gwilliam). The braided monoidal category of finite dimensional representations of the quantum group $U_{\hbar g}$ is equivalent to a subcategory of the braided monoidal category of modules for the $E_3$-algebra $\text{Obs}_{CS}$.

3. THE FOUR-DIMENSIONAL THEORY

The four-dimensional gauge theory we study is formally very similar to three-dimensional Chern-Simons theory.

We start with a four-manifold of the form $\Sigma \times S$ where $\Sigma$ is a Riemann surface and $S$ is a real two-dimensional manifold. Throughout the course of this seminar we will take $\Sigma$ to be either $\mathbb{C}$ or an elliptic curve $E$.

We also fix the data of a holomorphic one-form $\omega \in \Omega^{1,0}(\Sigma)$ that is no-where vanishing. The moduli space of the four-dimensional gauge theory consists of connections $A$ satisfying the following modified version of flatness

$$\omega \wedge F(A) = \omega \wedge \left( dA + \frac{1}{2} [A, A] \right) = 0.$$ 

Introduce local coordinates $(z, \bar{z})$ on $\Sigma$ and $(w, \bar{w})$ on $S$. Locally, a connection one-form looks like

$$A = A_z dz + A_{\bar{z}} d\bar{z} + A_w dw + A_{\bar{w}} d\bar{w}$$

In the flatness equation, note that the component $A_z$ never appears. Thus, we may as well restrict ourselves to connections of the form

(1) $$A = A_{\bar{z}} d\bar{z} + A_w dw + A_{\bar{w}} d\bar{w}.$$ 

We can then translate the flatness equation into the series of equations

$$\frac{\partial}{\partial w} A_{\bar{z}} + \frac{\partial}{\partial \bar{w}} A_w + [A_w, A_{\bar{z}}] = 0,$$

$$\frac{\partial}{\partial w} A_z + [A_{\bar{w}}, A_z] = 0,$$

$$\frac{\partial}{\partial \bar{w}} A_{\bar{z}} + [A_w, A_{\bar{z}}] = 0.$$ 

We draw the following conclusions:

- For each $w_0 \in S$ the connection one-form $A_{\bar{z}} d\bar{z}$ restricted to $\Sigma \times \{w_0\}$ determines the structure of a holomorphic principal $G$-bundle on $\Sigma$ (since every $g$-valued $(0,1)$-form on a Riemann surface determines a holomorphic principal bundle).

- The first equation above comes from the $\omega \Omega^0(\Sigma) \otimes \Omega^2(S)$ part of the curvature equation. It implies that for each $z_0 \in \Sigma$ the connection one-form $A_w dw + A_{\bar{w}} d\bar{w}$ restricted to $\{z_0\} \times S$ is flat.
The next two equations come from the component of the flatness equation living in $\omega \Omega^{0,1}(S) \otimes \Omega^1(\Sigma)$. Suppose that $\gamma : [0,1] \rightarrow S$ is a path from $\gamma(0) = w_0$ to $\gamma(1) = w_1$ in $S$. Then, we can view $\gamma$ as a map $\gamma : \Sigma \times [0,1] \rightarrow \Sigma \times S$. Then, these equation say that $\gamma^* A$ determines a homotopy between the holomorphic connections $(A \cdot dz)|_{w_0}$ and $(A \cdot dz)|_{w_1}$. In other words, the path $\gamma$ produces and isomorphism of holomorphic bundles over $\Sigma \times \{w_0\}$ and $\Sigma \times \{w_1\}$. Thus, we have a flat family of holomorphic bundles on $\Sigma$ parametrized by $S$.

The full space of fields of the four-dimensional theory is of the form
$$\Omega^{0,*}(\Sigma) \otimes \Omega^*(S) \otimes \mathfrak{g}[1].$$

The shift down by one amounts to the fact that we want to view the fields in degree zero as connection one-forms. Check that the degree zero piece precisely consists of those connections $(1)$. 

Most of this course will be concerned with the local setting where our four-manifold is of the form $\Sigma \times S = C \times \mathbb{R}^2$. When $\Sigma = C$ and $S = \mathbb{R}^2$ we will take for our holomorphic one-form $\omega = dz$, unless otherwise noted.

**Remark 3.1.** There are various variants of the theory just described. There is a version of this gauge theory defined on any complex surface $X$ equipped with some extra structure. For instance, the theory makes sense on all holomorphic symplectic manifolds.

### 3.1. The operators of the four-dimensional gauge theory

Analogously to the case of Chern-Simons, the main statement about quantum groups we aim to prove entails the operators of the four-dimensional gauge theory. Let’s consider the gauge theory placed on the four-manifold of the form
$$\Sigma \times (S^1 \times \mathbb{R})_w.$$ 

Of course, there are no global coordinates $z, w$, we just continue to use the notation to indicate that the theory is holomorphic on the Riemann surface $\Sigma$, and topological on $S^1 \times \mathbb{R}$. Just as in the case of Chern-Simons, we can look at solutions to the equations of motion that are constant along $\mathbb{R}$, to get some moduli space of connections on $\Sigma \times S^1$.

The analysis above says that for each point $t \in S^1$ the equation of motion dictate that we have a holomorphic bundle $V_t$ on $\Sigma$. As we go around the circle, monodromy along the flat connection in the $S^1$ direction implies that we obtain a non-trivial isomorphism of holomorphic bundles $\phi : V_0 \cong V_{2\pi}$. Thus, the moduli space of solutions to the equations of motion on $\Sigma \times S^1$ is (roughly)
$$M = \{\text{holomorphic bundles on } \Sigma \text{ with isomorphism}\}.$$ 

This moduli can also be identified with the space of “multiplicative Higgs bundles”. It’s also equivalent to the moduli of periodic monopoles on $\Sigma \times S^1$. This is a symplectic moduli space (in fact holomorphic symplectic), just as in the Chern-Simons case.

---

1 Dually, we can view the equations as saying we have a holomorphic family of flat bundles.
We will work formally near a trivial connection so that we may as well work on $\mathbb{C}^2 \times \mathbb{R}_t$. Deformations of the symplectic moduli space near the trivial connection are controlled by the dg Lie algebra

$$\Omega^0,\ast(\mathbb{C}) \otimes \Omega^\ast(\mathbb{R}) \otimes g.$$ 

Thus, if we perturb around the trivial connection, functions on the moduli space can be identified with

$$C^\ast(\Omega^0,\ast(\mathbb{C}) \otimes \Omega^\ast(\mathbb{R}) \otimes g).$$

The symplectic structure equips this space with a Poisson bracket. The quantum gauge theory concerns the deformation quantization for the bracket. We have the following picture, which we hope bears resemblance to the three-dimensional Chern-Simons picture.

\[
\begin{array}{c}
\mathcal{O}_h(M) \xrightarrow{\sim} C^\ast(\Omega^0,\ast(\mathbb{C}) \otimes \Omega^\ast(\mathbb{R}) \otimes g) \overset{\text{Koszul}}{\longrightarrow} \mathcal{Y}_h(\mathfrak{g}) \\
\mathcal{O}(M) \xrightarrow{\sim} C^\ast(\Omega^0,\ast(\mathbb{C}) \otimes \Omega^\ast(\mathbb{R}) \otimes g) \overset{\text{Koszul}}{\longrightarrow} \mathcal{U}(\mathfrak{g}[[z]]).
\end{array}
\]

Again, there is the problem of actually identifying the algebraic structure present in the deformation $C^\ast_h(\mathfrak{g}[z])$. This is the main objective of the course.

### 4. The Plan for the Course

We will mostly consider the four-dimensional gauge theory on $\mathbb{C}^2 \times \mathbb{R}_w^2$.

As pointed out in the last section, the quantum gauge theory produces a factorization algebra of observables $\text{Obs}^g$ on $\mathbb{C} \times \mathbb{R}^2$. This is the main object of study.

For each fixed $z_0$, one can restrict the factorization algebra $\text{Obs}^g$ to the submanifold $\{z_0\} \times \mathbb{R}^2_w$.

Denote this restriction by $\text{Obs}^g_{z_0}$.

**Lemma 4.1.** The factorization algebra $\text{Obs}^g_{z_0}$ is locally constant, and hence equivalent to an $\mathcal{E}_2$-algebra.

This is not just any $\mathcal{E}_2$-algebra, it is actually an augmented $\mathcal{E}_2$-algebra. This will be a very important property.

We now do something kind of funny: any $\mathcal{E}_2$-algebra can be considered as an $\mathcal{E}_1$-algebra. Viewing the $\mathcal{E}_2$-algebra as an algebra over the operad of little 2-disks, we can simply project the 2-disk onto a horizontal line. Thus, there is a forgetful functor from $\mathcal{E}_2$-algebras to $\mathcal{E}_1$-algebras, which we can think of as dg associative algebras (up to homotopy).

**Theorem 4.2** ([Tam03]). Suppose $A$ is an $\mathcal{E}_2$-algebra that is augmented as an $\mathcal{E}_1$-algebra. Then, its ($\mathcal{E}_1$) Koszul dual algebra $A^!$ has the structure of a Hopf algebra (up to homotopy).
This theorem does not directly apply to our situation. Our algebras are built from infinite dimensional vector spaces, and to discuss Koszul duality rigorously we must really take into account some natural filtration. Nevertheless, there is a modification of Tamarkin’s theorem that does apply.

We can now state Costello’s first theorem.

**Theorem 4.3 ([Cos])**. For any $z_0 \in \mathbb{C}$, the Koszul dual of the $E_2$-algebra $\text{Obs}_{z_0}^q$ is equivalent to the Yangian $\bar{Y}_h(g)$.

This implies the following statement for categories of modules. If $\text{Fin}(\bar{Y}_h g)$ denotes the monoidal dg category of finite-rank $\bar{Y}_h g$-modules, and $\text{Perf}(\text{Obs}_{z_0})$ denotes the monoidal dg category of perfect $\text{Obs}_{z_0}$-modules, then by the general yoga of Koszul duality, there is an equivalence of monoidal dg categories

$$\text{Fin}(\bar{Y}_h g) \simeq \text{Perf}(\text{Obs}_{z_0}).$$

Some formal manipulations in factorization algebras allow one to extract interesting consequences of this theorem. Here is one of them. Consider placing the factorization algebra $\text{Obs}_{z_0}$ on the punctured plane $(\mathbb{R}^2_w)^\times \subset \mathbb{R}^2_w$. Then, the pushforward of this along the radial projection

$$r : (\mathbb{R}^2_w)^\times \to \mathbb{R}_{>0}$$

has the structure of a one-dimensional locally constant factorization algebra. Hence, $r_* \text{Obs}_{z_0}$ is identified with a dg associative algebra. By work of Lurie and Francis-Ayala, this associative algebra is equivalent to the Hochschild homology

$$HH_* (\text{Obs}_{z_0}) \simeq r_* (\text{Obs}_{z_0}).$$

The Hochschild homology of any $E_2$-algebra is an associative algebra. Since pushforward and Hochschild homology is compatible with Koszul duality, we observe that the Theorem implies an equivalence of dg associative algebras

$$r_* (\text{Obs}_{z_0}) \simeq HH_* (\text{Obs}_{z_0}) \simeq HH_* (\text{Fin}(\bar{Y}_h g)).$$

We have just mentioned the first quasi-isomorphism. The second one follows from the fact that the Hochschild homology of any $E_2$ algebra $A$ is quasi-isomorphic as $E_1$-algebras to the Hochschild homology of its category of perfect modules. Further, $\text{Perf}(\text{Obs}_{z_0}) \simeq \text{Fin}(\bar{Y}_h g)$ by the main theorem.

This gives us an explicit way of realizing representations of the Yangian inside of the four-dimensional gauge theory. We can rightfully view $r_* (\text{Obs}_{z_0})$ as the value of the factorization algebra on a circle $\{z_0\} \times S^1_w$. Given a finite dimensional representation $V$ of $\bar{Y}_h g$ we can consider its trace

$$\text{Tr}_V : \bar{Y}_h g \to \mathbb{C}.$$ 

This trace is a character, hence determines an element $\text{Tr}_V \in HH_0(\text{Fin}(\bar{Y}_h g))$. This theorem implies that characters for the Yangian appear as “Wilson loops” in the four-dimensional gauge theory.
So far we have been primarily concerned with the factorization algebra in the topological \( \mathbb{R}^2 \)-direction. What extra structure does the factorization in the \( \mathbb{C} \)-direction buy us? Note that the theory is not locally constant in the \( \mathbb{C} \)-direction. In fact, it is holomorphic, so the factorization structure actually induces a sort of operator product expansion (OPE) just as in the theory of vertex algebras.

The way to codify this is to consider the operator product expansion between a small disk placed at \( z = z_0 \) and a small disk placed at \( z = z_0 + \lambda \), where \( \lambda \in \mathbb{C}^\times \). By holomorphicity, we can write the OPE as

\[
F_{\text{OPE}} : \text{Obs}_{z_0} \otimes \text{Obs}_{z_0} \rightarrow \text{Obs}_{z_0}(\lambda),
\]

where now \( \lambda \) plays a formal role. By the main theorem, we can identify this with a monoidal bifunctor of the form

\[
F_{\text{OPE}} : \text{Fin}(Y_h \mathfrak{g}) \times \text{Fin}(Y_h \mathfrak{g}) \rightarrow \text{Fin}(Y_h \mathfrak{g})(\lambda).
\]

**Theorem 4.4.** The map \( F_{\text{OPE}} \) encodes Drinfeld’s universal \( R \)-matrix

\[
R(\lambda) \in Y_h(\mathfrak{g}) \otimes Y_h(\mathfrak{g})(\lambda).
\]

Thus, the factorization product in the \( \mathbb{C} \)-direction encodes the universal \( R \)-matrix.

We can state this result in a more categorical framework as follows. We have just mentioned that the theory spits out a factorization algebra on \( \mathbb{C} \) with values in \( \mathbb{E}_2 \)-algebras. As above, every \( \mathbb{E}_2 \)-algebra admits a module category that is monoidal. In particular, we have a factorization algebra on \( \mathbb{C} \) with values in the monoidal category of modules. By the main theorem, this factorization algebra is equivalent to a factorization algebra on \( \mathbb{C} \) with values in the monoidal category of modules for \( Y_h \mathfrak{g} \). This witnesses a structure in the category \( \text{Fin}(Y_h \mathfrak{g}) \) that is not so obvious: in addition to being monoidal, it is also a chiral category.

To set up the analogy with Chern-Simons, consider the following. Placing Chern-Simons on the three-manifold \( \Sigma \times \mathbb{R} \) allows us to think about the theory as maps from \( \mathbb{R} \) to local systems on \( \Sigma \). At the level of factorization algebras, in the case \( \Sigma = \mathbb{R}^2 \), this says that we have an \( \mathbb{E}_1 \)-algebra with values in \( \mathbb{E}_2 \)-algebras. If we look at modules for the \( \mathbb{E}_2 \)-algebra, we obtain a \( \mathbb{E}_1 \)-algebra in \( \mathbb{E}_1 \)-categories, so an \( \mathbb{E}_2 \)-category.

We think about the Yangian as being equivalent to maps from \( \mathbb{C} \) to the moduli of flat connections on \( S = \mathbb{R}^2 \). On \( \mathbb{C} \), the theory is holomorphic, so we obtain a chiral, or vertex algebra, with values in \( \mathbb{E}_2 \)-algebras. Looking at modules, we get a chiral algebra in \( \mathbb{E}_1 \)-categories. This is what we should call a “chiral monoidal category”.
