Abstract. Rational curves are essential tools for classifying algebraic varieties. Bounding the dimensions of families of embedded rational curves with singularities of a particular type is naturally part of this classification. Singularities, in turn, are classified by their value semigroups. Unibranch singularities are associated to numerical semigroups, i.e. sub-semigroups of the natural numbers. These fit naturally into a tree, and each is associated with a particular weight, from which a bound on the dimension of the corresponding stratum in the Grassmannian may be derived. Understanding how weights grow as a function of (arithmetic) genus g , i.e. within the tree, is thus fundamental. We establish that for genus $g \leq 8$, the dimension of unibranch singularities is as one would naively expect, but that expectations fail as soon as $g = 9$. Multibranch singularities are far more complicated; in this case, we give a general classification strategy and again show, using semigroups, that dimension grows as expected relative to g when $g \leq 5$. This is joint work with Lia Fusaro Abrantes and Renato Vidal Martins.
